Abstract

Introduction: Despite the development and wide implementation of Directly Observed Therapy Strategies (DOTS), multidrug-resistant tuberculosis (MDR-TB) remains a serious global health threat. In this study, the role of host immune response in patients with MDR-TB is investigated and compared with that of patients with smear-positive drug-sensitive tuberculosis (SP-TB).

Material and methods: 27 patients with SP-TB, 20 patients with MDR-TB, and 20 healthy controls were included in the study. Immune parameters were determined by flow cytometry using monoclonal antibodies in order to compare the percentage values of these markers in the two study groups and the control group.

Results: The levels of lymphocyte subgroups in the gate of CD45(+)/CD14(–) lymphocyte: CD45(+), CD3(+), CD4(+) NK, CD3/HLA-DR, CD 95(+) cells were significantly lower; by contrast CD23(+), CD25(+), CD19(+), CD4(+)CD8(+) HLA-DR cells were found to be lower, but not significantly so in patients with MDR-TB, compared to levels in patients in the SP-TB and control groups. Besides these findings, the levels of NKT cells and γδ TCR(+) cells were significantly higher in the MDR-TB than in the healthy control and SP-TB group.

Conclusions: The lower levels of CD3/HLA-DR, CD4 (+), Fas (+), and NK, and the higher level of NKT together with γδ T cells in patients with MDR-TB compared to those in SP-TB may indicate a profound immune suppression in MDR-TB patients and thereby may denote an accumulation in the bacterial load. Our findings may shed light on the pathogenesis and prognosis of MDR tuberculosis, and may point towards the use of flow cytometry findings as an aid to early diagnosis in MDR-TB patients.

Key words: HLA-DR, γδ T cell, NK-T cell, multidrug-resistant tuberculosis.
Introduction

Despite the development of the directly observed therapy strategy (DOTS) multidrug-resistant tuberculosis (MDR-TB) is still an important problem that threatens global community health [1-3]. Nearly 50 billion people are infected with MDR-TB worldwide and the number is increasing every year as new cases are infected with MDR-TB strains [4].

Most of the risk factors for the emergence of drug resistance in tuberculosis are acquired. For example, inadequate treatment due to adverse drug reactions, economic hardships, and non-adherence to drug therapy when symptoms resolve may be responsible for the current high prevalence of MDR-TB.

In addition, there is a lack of clarity regarding the genetic control of tuberculosis which, if resolved, could help to explain why active tuberculosis disease only emerges in a relatively small number of infected people [5].

Protection against Mycobacterium tuberculosis (M. tbc) is based on cell-mediated immunity, most importantly involving CD4 (+) and CD8 (+) T-cell subsets [6]. The CD4 T cell is believed to be responsible for regulating the immune response to M. tbc. When activated, CD4 cells proliferate and produce cytokines which in turn activate mononuclear phagocytes to control the growth of intracellular mycobacteria [7].

The primary function of the CD8 (+) lymphocytes (T suppressor/cytotoxic) is the lysis and apoptosis of the infected cells. In some studies, it was found that in active tuberculosis patients, CD4 and CD8 counts are decreased, but the CD4/CD8 ratio is increased compared to the healthy population [8].

Findings in peripheral blood contrast with other research suggesting an increase in CD4 cells and a reduction in CD8 cells in bronchoalveolar lavage fluid leading to an increased CD4/CD8 ratio, particularly where there is moderate or advanced pulmonary involvement. The researchers attributed these findings to compartmentalization or sequestration of CD4+ lymphocytes in cases of high grade pulmonary TB [9].

The human leukocyte antigen (HLA) system is a powerful genetic marker. Host immune response and infectious diseases are genetically controlled by the HLA system [10].

In M. tbc infection, HLA factors are associated with the type and severity of the disease. Although immune suppression and the progress of disease are controlled by the HLA system, innate resistance to Mycobacterium infection appears to be dependent on non-HLA genes [11, 12]. However, genetic susceptibility of the host to multidrug-resistant tuberculosis (MDR-TB) is not fully understood [13].

In this study, we aimed to compare the levels of CD3+/HLA-DR, HLA-DR and lymphocyte subgroups (CD45, CD3, CD4, CD19, CD 23, γδ-T cell, NK-T) and the marker of apoptosis Fas (CD95) in smear-positive drug-sensitive tuberculosis (SP-TB) with these values in smear-positive MDR-TB cases.

Where the immune profiles of the two groups were different, the effect of immune status in the development and clinical progress of MDR-TB was examined.

Material and methods

Patients and study design

20 healthy controls, 27 patients with sputum smear-positive pulmonary tuberculosis sensitive to primary anti-TB therapy, and 20 patients with sputum smear-positive MDR-TB were included in the study.

All of the cases were HIV (–). In the MDR-TB group, two of the cases had not been previously treated with anti-tuberculosis agents (primary MDR), while 18 of the cases had been treated at least two times before the study (secondary MDR).

Where possible, patients without any co-morbidities were selected. In all cases, baseline data such as history (both medical and family histories, including TB family history), physical examination, biochemical parameters and complete blood count (particularly haemoglobin [Hb], haematocrit [Htc] and leukocyte values) were recorded.

Mycobacterium tuberculosis was isolated from the sputum and cultured according to the standard techniques, and sensitivity testing was performed using the absolute concentration method [14, 15].

Immune profile determination

The patients’ immune profiles were determined by analyzing blood samples, by whole blood lysis on flow cytometry (Becton-Dickinson FACScalibur, San Jose, CA) following heparinization and treatment with fluorochrome-conjugated monoclonal antibodies (anti-human IgG1-FITC/IgG2a PE isotype control, anti-human CD45-FITC, CD3-FITC, CD4-FITC, CD8-PE, CD19-PE, CD16/56-PE(NK), HLA-DR, CD23-PE, CD25-FITC, Fas(CD95)-PE and γδ-T cell-PE). In order to detect the changes in percentage values of these markers, first 100 μl of heparinized blood was placed into all test tubes, and then 10 μl of isotype control was added into one tube and 10 μl of monoclonal antibody into the others. After incubating for 30 min at room temperature in a dark room, erythrocytes were removed using 500 μl of erythrocyte lysis buffer and 5 ml of phosphate buffer saline (PBS) to wash the solution twice before centrifuging for 5 min at 1850 rpm. Then a sample containing 10,000 cells from each tube was counted in the appropriate lymphocyte gate using flow cytometry equipped with
a CELLQuest software program. Finally, the percentage value of all the markers was determined using the analysis program.

Statistical analysis
Statistical analysis was conducted using Unistat 5.1 software. All numerical values are reported as means ± SD. A comparison of variables between three groups was performed using one-way ANOVA. Differences between control, SP-TB and MDR-TB groups were determined by the Bonferroni test. Chest X-ray, family and TB history groups were estimated by $\chi^2$ test. $P$-values less than 0.05 were considered significant.

Results
Patients’ demographic details
As can be seen in Table I, leucocytes counts were found to be significantly different between groups and increases were observed in both SP-TB and MDR-TB groups. Haemoglobin and haematocrit levels were found to be increased in the SP-TB group and decreased in the MDR-TB group, compared to the control group. Most of the MDR-TB patients had a positive family TB history, while less distinct family histories of tuberculosis were noted in SP-TB and control groups, as shown in Table I.

Flow cytometric analysis
CD4, CD3, Fas (CD95), CD3/CD25 and CD3/HLD-DR expressions were found to be significantly decreased in both SP-TB and MDR-TB groups compared to the control group (Figures 1, 2). In contrast to these findings, NKT (CD3 (+) and $\gamma\delta$ T cell levels were found to be significantly increased, while CD8 levels were non-significantly increased, in both SP-TB and MDR-TB groups compared to the control group, as shown in Figures 1 and 2.

CD45, CD19, CD16/56 (NK), HLA-DR, CD4/CD8 and CD3/CD23 levels were found to be increased in the SP-TB group and significantly decreased in the MDR-TB group compared to the control group (Figures 1, 2).

Discussion
The latest WHO estimates indicate that between 250,000 and 500,000 new MDR-TB cases occur annually, which accounts for 3-6% of all new and
previously treated TB cases. These figures indicate an upturn in the proportion of resistant isolates and the authors of the review also confirm the emergence of extensively resistant TB which includes resistance to fluoroquinolones and aminoglycosides [16]. The emergence and spread of drug resistance is widely recognized as posing a public health threat of global proportions. There is a clear correlation between late diagnosis of disease which causes a delay in initiating effective treatment, and unsuccessful clinical outcomes [17]. For this reason, immunological testing may have an important role in enabling prompt diagnosis and treatment of tuberculosis.

The total blood leukocyte counts and total lymphocyte (CD45) levels of patients varied between all the groups; and particularly when the MDR-TB and the SP-TB group were compared the difference was statistically significant. Leukocyte levels were higher in patient groups compared to controls, while CD45 counts were lowest in the MDR-TB group. This level represents a small proportion of the total leukocyte numbers in patients with MDR-TB, thus indicating the presence of lymphopenia. This low CD45 level in the MDR-TB group draws attention to these patients’ reduced lymphocyte response, compared to that of the SP-TB group. In addition, the lymphopenia observed among patients with MDR-TB may play an important role in the pathogenesis of the disease.

The lowest levels of both HLA-DR and CD3/HLA-DR were seen in the MDR-TB group. These measurements reflect the low level of active lymphocytes in patients with MDR-TB. Our findings are also consistent with a study by Rodriguez et al., which did not find any statistically significant difference in the HLA-DR (+) expression index in PPD (–), PPD (+), active tuberculosis, or treated tuberculosis groups [8].

In patients with MDR-TB, CD4 (+) T lymphocyte counts have been observed to be low. On the other hand, some studies indicate that CD3 (+) and CD4 (+) cell counts may be higher in drug-sensitive pulmonary TB cases [18, 19].

T lymphocytes, especially CD4 (+) T lymphocytes, play an important role in the immune reaction against MDR-TB. It is not clearly known whether the effects of CD4 (+) lymphocytes to control disease are mediated by their cytokine secretions or their...
direct effect on macrophages. Indeed there are many inter- and intracellular processes involved; and if some of these mechanisms can be elucidated, new treatment strategies may be developed.

One of the aims of our study was to find out whether we could predict the development of MDR-TB by looking at the HLA-DR and CD3/HLA-DR levels. When the three groups were compared, although the differences between the HLA-DR levels were not significant, a significant difference was found in CD3/HLA-DR levels for patients with MDR-TB.

CD8 (+) T cells are essential for host defence against intracellular bacterial pathogens such as M. tub. [18, 20]. Yildiz et al. found significantly lower values of lymphocyte numbers, absolute numbers and percentages of CD3 (+) and CD4 (+) in MDR-TB cases when compared to SP-TB cases. Besides this, the CD4/CD8 ratio was lower in MDR-TB cases compared to SP-TB cases, but these results were not statistically significant [21]. In our study, while not statistically significant, the high levels of cytotoxic CD8 (+) lymphocytes in patients with MDR-TB may be secondary to the stimulation of tuberculoid antigens. Alternatively an increase in CD8+ supports the suppression reflected in the reduction of the CD4/CD8 ratio from 1.44 in the control group, and 1.36 in the SP-TB group to 1.08 in the MDR-TB group.

Levels of the CD19 (+) B lymphocytes responsible for antibody production and their activation receptor CD23 were non-significantly lower in the MDR-TB group. This suggests that humoral as well as cellular immunity is affected, and that this effect is more profound in the MDR-TB group than the SP-TB group. Similarly, Cagatay et al. showed that both humoral and cellular immune response is suppressed in patients with MDR-TB [22].

Fas (CD95)(+) lymphocytes were found to be significantly lower in MDR-TB patients compared to the control group and the SP-TB patients. Fas (CD95)(+) lymphocyte is typical for patients with prognostically unfavourable immune abnormalities. It is tempting to speculate that apoptosis of T cells (possibly Th1 cells) is of great importance in the pathogenesis of the immunodeficiency associated with the mycobacteriosis [23]. In our study, Fas (CD95)(+) among the three groups was highly significant, with patients with MDR-TB demonstrating the lowest level. This may indicate suppression of the host immune response and may help to shed light on MDR-TB pathogenesis.

In our study, NK (CD16/56) cells were increased in the SP-TB group compared to healthy controls. On the other hand, when compared to both controls and the SP-TB group, the MDR-TB group demonstrated a profound reduction in NK levels, indicating a dysfunctional NK response. Yildiz et al. demonstrated that patients with MDR-TB had significantly lower NK compared to normal TB and controls. This reduction in NK may suggest a role for impaired NK function in the pathogenesis of MDR-TB [22, 23].

The level of human natural killer T cells (NKT) is a non-invasive marker of pulmonary TB activation and disease prognosis. The reason for a higher level of NKT in tuberculosis patients might be related to the high load of phosphorylated metabolites released following the phagocytosis of bacilli by macrophages [24-26].

In this study, both groups of patients with TB had significantly raised NKT levels, indicating an active infection and a host immune protective response against mycobacteria compared to healthy controls. Thus, the NKT cell increase is consistent with the presence of active infection as seen in our patients. In addition, NKT levels may shed light on disease progression and prognosis, and help to distinguish MDR-TB from SP-TB disease. The mucosal immune system showed a similarly significant increase in both SP-TB cases and in patients with MDR-TB. Lockhart et al. and Lee et al. demonstrated that in infection with Mycobacterium, γδ T cells become dominant as they are activated by phosphorylated metabolites within phagosomes [27, 28]. In our study, there was a significant increase in the level of γδ T cells in the MDR-TB group compared to the control and SP-TB groups.

To summarize these flow cytometric findings, MDR M. tub. modifies host defence by suppressing CD8 lymphocytes and NKT cells and increased levels of γδ T cells detected by flow cytometry in MDR-TB patients compared to drug-sensitive TB patients. This may also be possible to gain valuable information by measuring the immune parameters of individuals who had contacted patients with a family history of MDR-TB.

In conclusion, decreased levels of CD4, CD3/HLA-DR+ and Fas + T cells and increased levels of NKT and γδ T cells detected by flow cytometry in MDR-TB cases compared to drug-sensitive TB patients might have diagnostic value. Based on immunological profiles it may be assumed that the patient has developed MDR-TB, and so without the two-month delay of culture and sensitivity testing, empirical therapy may be started. This proposition of course remains to be confirmed by further research and tested in clinical practice.
