Introduction

Gliomas are the most common primary brain tumours. According to the most important features, i.e. vascular proliferation, degree of cellularity/atypia, and necroses, they are classified into four WHO grades. Glioblastoma multiforme (GBM) is the grade 4 glioma derived from astrocytes. It constitutes about 55% of all gliomas, and is more common in male Caucasians. The prognosis in GBM is extremely poor with median survival rate about 10-15 months and 75% mortality rate in the first 1.5 year from diagnosis. Histopathologically there are two subgroups of glioblastoma, primary (‘de novo’) and secondary (from the lower grade glioma) glioblastoma. Despite years of investigations, the treatment of glioblastoma is still unsatisfactory [1]. New agents are being investigated.

Significant development of diagnostic methods based on molecular techniques and neuroimaging has changed the knowledge concerning diagnosis and treatment of central nervous system neoplasms. Glia-derived primary brain tumours have become a dynamic area of molecular studies. Information from molecular diagnostics may have crucial importance in the diagnostic and treatment process.

The way to improve the efficiency of chemotherapy of malignant gliomas may be the combined administration of alkylating agents and those target-ed at epithelial growth factor receptor (EGFR). The patients eligible for such therapy should show hypermethylation of MGMT (O6-methylguanine-DNA-methyltransferase) promoter as well as amplification of EGFR.

Material and methods

21 consecutive cases of glioblastoma multiforme were studied: patients (W 65%, M 35%, age average 51 y) operated on in the Neurosurgery Department of Jagiellonian University Medical College (JUMC) and neuropathologically diagnosed in the Department of Neuropathology, Chair of Pathomorphology, JUMC in Cracow. The methylation status of the MGMT promoter was determined by methylation-specific PCR (MS-PCR). Before MS-PCR, genomic DNA was treated with sodium bisulphite, purified, denatured, precipitated and eluted. EGFR amplification was investigated using the FISH method.

The patients eligible for such therapy should show hypermethylation of MGMT (O6-methylguanine-DNA-methyltransferase) promoter as well as amplification of EGFR.

Material and methods

21 consecutive cases of glioblastoma multiforme were studied: patients (W 65%, M 35%, age average 51 y) operated on in the Neurosurgery Department of Jagiellonian University Medical College (JUMC) and neuropathologically diagnosed in the Department of Neuropathology, Chair of Pathomorphology, JUMC in Cracow. The methylation status of the MGMT promoter was determined by methylation-specific PCR (MS-PCR). Before MS-PCR, genomic DNA was treated with sodium bisulphite, purified, denatured, precipitated and eluted. EGFR amplification was investigated using the FISH method.

O6-methylguanine methyltransferase (MGMT) promoter methylation analysis with methylation-specific PCR (MS PCR)

Tissue samples, not immersed, frozen to the temperature of –80°C directly after tumour resection were used for analysis.

DNA isolation sterile removed tissue was fragmented, placed in a 1.5 mL Eppendorf tube, fast-frozen in liquid nitrogen and kept at a temperature of –80°C. The genomic DNA isolation from the tumour and from the control tissue was performed using the QIAamp DNA Mini Kit (Qiagen GmbH, Germany) according to the manufacturer’s protocol.
MGMT promoter methylation detection:

Using the methylation-specific PCR (MSP) method, the level of methylation in the CpG-rich DNA region of the MGMT gene promoter was evaluated. The applied method is based on the chemical modification (deamination) of the DNA sample with sodium bisulphite. In this reaction unmethylated cytosine is changed to uracil, and in PCR finally to thymine.

Three or more orange signals with two green signals for chromosome 7 indicates reactions (32 cycles) were performed including an initial denaturation of 10 min at 95°C and subsequent denaturation for 45 s at 95°C, annealing for 45 s at 62°C and extension for 1.5 min at 72°C. PCR reactions were performed in 30 µl of 25 mM MgCl₂, with 1.2 µl dNTP (Applied Biosystems Inc.), 20 µM of each primer and 0.5 µl Gold Taq DNA Polymerase (Applied Biosystems Inc.) Amplification products were separated on 2% agarose gel (110 V, approx. 25 min) and visualized by ethidium bromide staining.

Epidermal growth factor receptor (EGFR) amplification analysis with the FISH method

FISH was done on 4-5-µm-thick formalin-fixed paraffin-embedded tissue sections (FFPE) using Paraffin Pretreatment Kit (No.32-80120) and LSI/EGFR/CEP 7 FISH Probe kit (No. 32-191053, Vysis, Inc., Downers Grove, IL, USA). The kit uses a dual-color probe for determining the number of copies of EGFR gene (labelled with SpectrumOrange dye) and the centromeric region of chromosome 7 (7p11.1-q11 Alpha Satellite DNA) is labelled with SpectrumGreen dye. In brief, tissue sections were deparaffinized and dehydrated in 100% ethanol and air dried. Slides were then pre-treated with 0.2 M hydrochloric acid for 20 minutes (RT), immersed in Pretreatment Solution at 80°C for 30 minutes and digested in protease solution for 27 minutes at 37°C. Then 8 µl of probe was applied on tissue sections and the slides were denatured (72°C for 5 minutes), hybridized at 37°C overnight in hybridizer MP-16 (Hiperon, Genos). After hybridization, the slides were washed with Post-Hybridization Wash Buffer (2xSSC, 0.3% NP-40, pH 7.0-7.5) at 72°C for 3 minutes. The slides were air-dried and 4'-6'-diamidine-2'-phenylindole (DAPI) counterstain was applied. Samples were evaluated with the Nikon fluorescence microscope. For the normal numbers of copies of the EGFR gene and chromosome 7, two orange and two green signals should be observed, respectively. Three or more orange signals with two green signals for chromosome 7 indicates extra copies of the EGFR gene (EGFR amplification). More than two green signal in the nucleus means polyploidy.

Results

The results are summarized in Table 1. 10/21 (47.6%) cases showed MGMT promoter hypermethylation and 8/21 (38.1%) showed amplification of EGFR.

According to the MGMT promoter methylation and EGFR amplification status the investigated patients form four groups:
- MGMT promoter methylation and EGFR amplification present: 4/21 (19.04%) (an example illustrated in Fig. 1),
- MGMT promoter methylation present, no EGFR amplification: 6/21 (28.6%) (an example illustrated in Fig. 2),
- no MGMT promoter methylation, EGFR amplification present: 4/21 (19.04%) (an example illustrated in Fig. 3),
- no MGMT promoter methylation, no EGFR amplification: 7/21 (33.3%) (an example illustrated in Fig. 4).

Discussion

Tumour histopathology and neoplastic cells’ sensitivity to different strategies of treatment seem to be associated with specific molecular features. It should be reasonable to adjust the treatment approach to the particular molecular tumour phenotype and this is the idea of personalized therapy in oncology. At least three molecular markers of clinical significance in gliomas are already indentified: O6-methylguanine methyltransferase (MGMT) promoter methylation, 1p/19q codeletion, and isocitrate dehydrogenase-1 mutations (IDH1). All of them are favourable prognostic factors, and some also have predictive value. Also the classic molecular markers of cancerogenesis, such as p53 status and epidermal growth factor receptor (EGFR) amplification, are discussed in gliomas [2].

MGMT promoter methylation

O6-methylguanine methyltransferase is a DNA repair protein. Its function is to remove the alkyl group from the O6-guanine position to prevent DNA failure and cell death. MGMT promoter hypermethylation stops the MGMT transcription. Theoretically, it makes the neoplastic cells’ DNA more sensitive to damage from alkylating agents. In conclusion, MGMT promoter methylation has potential predictive value for this type of chemotherapy (e.g. with temozolomide).

Clinical trials have already been undertaken to investigate the correctness of this approach. Thus, in the EORTC trial 22033 – 26033 primary chemotherapy with temozolomide v. radiotherapy alone in grade II WHO astrocytic brain tumours has been compared. MGMT status in those patients (stratified for 1p loss already) has been assessed to determine whether MGMT promoter methylation affects the benefit from temozolomide therapy. In the CATNON trial (anaplastic gliomas) four patient groups according to 1p/19q loss and MGMT promoter methylation have been designed and the efficiency of temozolomide in the concurrent, adjuvant or definitive settings of treatment was investigated [3]. The CODEL project, focused on the newly diagnosed anaplastic oligodendrogliomas and anaplastic mixed gliomas with 1p/19q codeletion, compared three strategies of treatment: radiotherapy alone, temozolomide chemotherapy alone, and radiochemotherapy with temozolomide [4].

The most powerful results, according to newly diagnosed glioblastoma patients’ management, have been obtained in the EORTC NCIC trial. The EORTC NCIC investigators reported an increase of the median survival (from 12.1 to 14.6 months) and of the two-year survival rate (from 10 to 26%) for patients treated with combined radio- and chemotherapy with temozolomide. They were able to present a signifi-

*MET – MGMT promoter methylation present; UNMET – no MGMT promoter methylation
Co-occurrence of MGMT gene promoter methylation and amplification of EGFR in glioblastoma

Significant difference in progression-free survival among the MGMT promoter methylation group—those treated with radiochemotherapy (temozolomide) have had progression-free survival of 10.3 months vs. 5.9 months (radiotherapy alone). It suggests that the MGMT promoter methylation is a positive predictive factor in temozolomide therapy for glioblastoma in newly diagnosed patients. Since then, radiotherapy alone has no longer been an accepted standard of treatment in newly diagnosed glioblastoma. MGMT promoter methylation study showed promising results in the CENTRIC trial also. This project has investigated cilengitide—a first-in-class integrin targeting polypeptide. It was found that MGMT methylated glioblastoma patients (30–35%) responded with a gain in the progression-free survival from the combined radiochemotherapy (temozolomide plus cilengitide) [5].

The molecular findings are expected to be useful in clinical conditions to facilitate decisions as for the treatment of choice. MGMT promoter methylation is already an advocated factor in the treatment decisions in glioblastoma patients. Based on the MGMT status the homogeneous groups of patients most likely to benefit from the particular treatment (alkylating agents) are defined. Unfortunately, available data do not support any particular treatment in relation to the molecular features of the tumour. The implementation of MGMT status evaluation into the glioblastoma treatment process requires standardization of the MGMT methylation assessment techniques; for now it is deemed that only methylation-specific PCR can provide repeatable, clinically useful information, whereas all other methods are of experimental value. Moreover, even MS-PCR has not met criteria of reproducibility across the laboratories and the necessity of validation of protocols has been stressed [6]. As a result, MGMT methylation status evaluated in this way cannot be regarded as the conditioning factor for temozolomide (the only proven active agent against glioblastoma) [2].

The current routine histopathological diagnosis of high-grade gliomas does not enable ideal correlation with the outcome; therefore it is expected that the molecular features may help to expand or substantially contribute to glioma classification. It is well known that the anaplastic glioma studies need 1p/19q codeletion and MGMT promoter methylation stratification (CATNON, CODEL) and the newly diagnosed glioblastoma trials need MGMT promoter status evaluation (CENTRIC); both molecular markers carry

---

**Fig. 1.** MGMT promoter methylation and EGFR amplification present (enhanced orange signal due to EGFR gene multiplication)

**Fig. 2.** MGMT promoter methylation present, no EGFR amplification (characteristic pairs of orange and green signal for both investigating and control molecular probe of EGFR gene detection—normal number of EGFR copies)

**Fig. 3.** No MGMT promoter methylation, EGFR amplification present (orange signal for EGFR gene multiplication)

**Fig. 4.** No MGMT promoter methylation, no EGFR amplification (as in Fig. 2, orange and green signals form pairs)
a strong prognostic value, which independently influences the patients’ outcome [2]. Especially the associations between different molecular biomarkers require further investigations (e.g. 1p/19q codeletion and IDH1 mutations are extremely rare in glioblastomas and might even be considered as incompatible with the diagnosis of glioblastoma in the future) [7, 8]. A very basic and still important question is the range of MGMT promoter methylation in the glioblastoma. In our series of unselected and consecutive cases of GBM, 10/21 (47.6%) showed MGMT promoter hypermethylation. This result is similar to other reports [9].

**EGFR amplification**

Epidermal growth factor receptor (EGFR) amplification in glioblastoma has been widely investigated [10-16]. EGFR amplification and overexpression is a part of the molecular pathway leading to secondary glioblastoma development. EGFR overexpression has been found in 40–50% of glioblastoma cases and is a sign of late tumour progression linked to clinical malignancy. For this reason, EGFR amplification is considered an unfavourable prognostic factor in glioblastoma. In about 50% of tumours with EGFR amplification variant III of EGFR is amplified, which carries worse prognosis in terms of a poorer survival rate and shorter interval to clinical relapse [10]. Increased EGFR amplification seems to be related to increased tumour cell proliferation and immortality (resistance to apoptosis), migration, angiogenesis and infiltration. All of those result from the pathological continuous EGFR receptor activity and consequently activation of the PI3-K/Akt pathway and MAPK/extracellular signal-regulated kinases 1/2 (ERK1/2) pathway [11]. EGFR signalling inhibition looks promising as a treatment option in glioblastoma. It is possible in different ways: by monoclonal antibodies blocking the ligand site in the tumour cell membrane that leads to receptor internalisation, by ligand-toxin/radioimmuno agents, by intracellular tyrosine kinase inhibitors (EGFR-TKI), or else by decrease of EGFR expression (antisense oligonucleotides, ribozymes and small interfering RNA) [10-15]. The clinical trials of EGFR-TKI erlotinib and gefitinib are ongoing. The first results are controversial [8, 13-16]. While in one study the satisfactory result of treatment was strongly associated with EGFR overexpression [11], in another this correlation could not be confirmed [13]. Recently Peerboom et al. reported negative results of bi-modal adjuvant treatment of GBM with temozolomide and the EGFR inhibitor erlotinib [16], though it seems that the question has not been definitely solved and the proper selection of patients for treatment remains a crucial factor.

To sum up, the known glioblastoma molecular status gives the possibility to define a homogeneous group of patients most likely to benefit from the particular way of treatment. The investigation of the co-occurrence of MGMT methylation status and amplification of EGFR could result in the recruitment of patients potentially sensitive to both temozolomide and anti-EGFR agents and thus in the definition of a more ‘pharmacologically homogeneous’ group. Our results suggest that both MGMT methylation and EGFR amplification segregate independently. These results do not differ significantly from those of Prerana et al., who found EGFR amplification in 30.4% of GBMs with MGMT hypermethylation (in our material – 40%), and in 42.1% of cases without MGMT hypermethylation (in our material – 36.4%) [7]. In our study in about 19% of cases it was possible to show both molecular biomarkers and therefore supposedly we may estimate that approximately at least 1/5 GBM patients could benefit from the combined treatment with temozolomide and one of the agents acting via EGFR.
