Summary Background. An obstetric fistula is both an unfortunate and annoying preventable complication that follows poorly managed prolonged obstructed labor. Despite an improvement in obstetric management, this condition has remained with us in developing countries partly because of the failure of effective maternity care, as well as lack of adequately trained surgeons to repair the backlog of cases.

Objectives. This study was therefore designed to determine whether a simpler and quicker method of fistula repair – saucerization – could be recommended for fistula repair by relatively inexperienced surgeons as compared to the more technical dissection method, which requires a higher level of surgical expertise.

Material and methods. This was an intervention analytical study of 77 fistula repairs done between 2010 and 2013 using either saucerization or dissection methods. The success (closure) rate for each method was calculated. A test of association between surgical technique and outcome of surgery using the chi-squared test was done. Residual fistulae dimensions and degree of scarring were assessed and analyzed using SPSS version 20.

Results. The dissection method had a higher, though not statistically significant, cure rate than the saucerization method (92.3% vs 76.3%, $p = 0.053$). Residual fistulae dimensions were larger in the saucerization group, while fibrosis was higher in the dissection method.

Conclusions. The saucerization technique for the repair of VVF was inferior to the dissection method, although the difference in cure rate was not statistically significant.

Key words: dissection, obstetric fistula, vesicovaginal fistula.

Umoyioho AJ, Olatunbosun OA. Saucerization versus dissection on the repair of vesicovaginal fistulae. *Fam Med Prim Care Rev* 2017; 19(4): 408–411, doi: <https://doi.org/10.5114/fmPCR.2017.70817>.

Background

A vesicovaginal fistula (VVF), especially an obstetric fistula, is an obstetric calamity prevalent only in developing countries. It is a major public health problem in Nigeria, a reminder of gender inequality and a reflection on the poor state of the health care system in affected countries.

An obstetric fistula is an abnormal connection between the genital tract and the urinary bladder and/or rectum arising from prolonged obstructed labor [1], leading to continuous and uncontrolled leakage of urine, often as a result of poor or insufficient emergency obstetric care and a skilled birth attendant [2, 3].

Those women affected live with persistent urinary and/or fecal incontinence, which, with the accompany stench, leads to social isolation, divorce, depression and even abuse. They lose their self-esteem and are ostracized from their home and society [4].

An estimated 2 million women are said to be living with untreated obstetric fistulae globally, while approximately 50,000–100,000 new cases of fistulae occur annually [5]. Unfortunately, most of these cases occur in developing countries, especially Sub-Saharan African and parts of Asia [5, 6].

In 2008, the Nigeria demographic health survey put the prevalence of obstetric fistulae at 0.5% in South-South Nigeria, a value higher than the national average of 0.4% [7]. A total of

400,000–500,000 cases of VVF are estimated to be in Nigeria, with about 20,000 new cases occurring every year [8]. The unmet need for fistula repair has been estimated to be as high as 99% [4], and most women/girls with fistulae have been predicted to die without receiving treatment [9]. According to a study entitled: survey and needs assessment, approximately 2,000–4,000 fistula repair surgeries are carried out yearly in Nigeria [5]. Based on this rate of repair, it has been estimated that it will take 100 years to deal with the backlog of cases, ignoring new cases [8]. This is also against the backdrop that only about 33 surgeons provide fistula repair services in Nigeria [10]. The surgical closure rate of vesicovaginal fistulae has been reported to be as high as 90%, though this rate varies from one repair hospital to another [2, 11]. The successful repair of a fistula depends on the experience of the surgeon, as well as the use of an appropriate technique. Other factors are fistula site, number, size and degree of scarring, as well as number of previous attempts at repair and post-operative care [12]. The first author of this study, in his earlier work, had developed a prognostic scoring system that helped with patient selection, an important factor that influences the surgical success rate [13].

Surgical management of fistulae is either through the abdominal or vaginal route. The preferred route of repair of obstetric VVF for most fistula surgeons in these setting is the vaginal approach [14]. The vaginal route offers the advantage of avoidance of laparotomy, thus preventing bowel manipulation, shorter recovery time, lesser morbidity, blood loss and

postoperative bladder irritability, as well as less postoperative pain [15].

Transvaginal repair of VVF involves two main surgical techniques – the saucerization and dissection method. Saucerization is used for small and residual fistulae. It offers the advantage of simplicity. It avoids a difficult layer dissection and produces very little vaginal shortening [16]. Despite these advantages, saucerization has the disadvantage of having less success, especially for fistulae with fibrosis.

Objectives

This study was carried out to assess the success rate achievable using these two different techniques and to see if saucerization can be recommended for surgeons with less experience.

Material and methods

Study design

This was an interventional analytical study of VVF repairs done by the first author. Seventy-seven obstetric fistula patients were randomly assigned to either the saucerization or dissection group. The two groups were matched for age, parity, duration of fistula and size of fistula.

Study setting

The study was carried out at the Family Life Center, Mbirit Itam in Akwa Ibom State, Nigeria, between January 2010 and December 2013. The Family Life Center is the Medical Missionary of Mary Mission Hospital, located at the outskirts of Uyo. It serves as a referral center for VVF cases in the state, as well as the neighboring states of Abia, Cross River, Rivers, Imo and Benue.

Participants

Ethical approval was obtained from the institution review board of the hospital, with registration number IRB/13/17. Cases were selected from among fistula patients that presented for fistula surgery during the study period. The cases were randomly assigned to the two groups (saucerization and dissection) by balloting. The first patient in each pair was assigned to either of the two groups by balloting, while the second patient was placed in the other group. Cases were selected using the prognostic scoring system [13]. A score of ≤ 4 means a simple VVF. The inclusion criteria included a small size fistulae < 4 cm, midvaginal fistulae and minimal scarring.

The exclusion criteria included juxtacervical (high) fistulae, because of the difficulty in saucerizing such fistulae, fistulae > 4 cm, juxtaurethral fistulae and fistulae where the ureteric orifice is less than 2 cm from the fistula margin.

Variables

The outcome measures for this study were:

- 1) the success rate (restoration of continence), i.e. closure of the fistula,
- 2) the dimension of residual fistulae at 3 months using calipers and a ruler,
- 3) subjective assessment of the degree of scarring by the first author.

The exposure variables were the two surgical techniques used during the study. The techniques of repair were the saucerization and dissection methods. The saucerization method is useful for small fistulae. It does not involve the separation of the vaginal layer from the underlying bladder wall. The edges of the fistula are trimmed off obliquely, stopping short of the blad-

der mucosa, thus converting the cylindrical track into a shallow saucer. The defect is then closed in two layers. The first row is placed in the bladder wall just superficial to the mucosa. This is followed by a second row in the vaginal wall [16]. The dissection method, on the other hand, entails dissecting the vaginal wall off the underlying bladder so that the bladder wall around the fistula can be mobilized and drawn across the defect. The bladder wall is repaired in two layers. Potential confounders include stress urinary incontinence and detrusor instability. These were ruled out through detailed history taking and examination of the patients.

Data sources/measurement

The variables measured were the age and parity of the patients. These were obtained from their case notes. The outcome variable (closure of fistula) was determined at 3 months, from history of whether or not the patient still leaks urine and during vaginal examination to rule out stress incontinence and detrusor instability. If a residual fistula is diagnosed, the widest dimension is measured using a ruler and a subjective assessment of the degree of fibrosis noted. The measurement and subjective assessment were done for both groups using the same instrument and by the same person to allow for comparability of measurements.

Bias

The potential for bias during selection of cases to either the dissection or saucerization group was minimized by randomly selecting them through balloting. The surgeries, either by the dissection or saucerization methods, were also carried out by the same surgeon, thus removing the bias that would have arose if surgeons with different surgical skills had done the operations.

Study size

The sample size was determined by the number of eligible fistula patients that presented during the study period.

Quantitative variables

These included age and parity of the patients and the sizes of the residual fistulae. Because of the wide spread of the ages and for ease of data management and analysis, the ages were grouped into six categories with a class width of five. Parity and residual fistula size were analyzed ungrouped.

Statistical methods

The data generated was analyzed using SPSS version 20, and the results were expressed in numbers and percentages. Descriptive analysis was performed using means, percentages and ranges. The variables (age, parity and residual fistula size) were checked for normal distribution using a combination of statistical tests, which included the Kolmogorov–Smirnov test, skewness, kurtosis and their critical values. These tests show that these variables are normally distributed. The chi-squared test was used to test for any association between categorical variables, such as surgical technique and outcome of repair. Association was considered significant at a p -value of less than 0.05. A paired sample t -test for the mean difference of fistula sizes before repair and post-repair were also carried out.

Results

Participants

During the period under study, 123 patients with incontinence presented for surgery. History taking and examination

revealed that only 115 of the women had fistulae, while 8 had a combination of stress incontinence and detrusor instability. Of the 115 patients examined for eligibility, 77 were eligible and were included in the study and analysis. All participants in the study presented for a follow up.

Descriptive data

Table 1 shows the demographic characteristics of the patients. The age, parity and residual fistula size of the patients shows normal distribution. The age ranges of the women were 17 to 36 years. Their mean ages were: 25.4 years (SD 5.8) and 25.6 years (SD 5.2) for the saucerization and dissection groups, respectively, while the average parity was 3.5 (SD 1.7) and 3.3 (SD 1.7), respectively. A majority of the women were married.

Table 1. Demographic characteristics of VVF patients

Age	Saucerization		Dissection	
Years	<i>n</i>	%	<i>n</i>	%
< 15	0	0.0	0	0.0
15–20	8	21.0	6	15.4
21–25	10	26.3	12	30.8
26–30	12	31.6	13	33.3
31–35	5	13.2	6	15.4
> 35	3	7.9	2	5.1
Total	38	100.0	39	100.0
Parity	<i>n</i>	%	<i>n</i>	%
1	7	18.4	9	23.1
2	2	5.3	4	10.3
3	10	26.3	7	17.9
4	11	28.9	9	23.1
5	3	7.9	6	15.4
> 5	5	13.2	4	10.3
Total	38	100.0	39	100.0
Marital Status	<i>n</i>	%	<i>n</i>	%
Married	34	89.5	36	92.3
Single	4	10.5	3	7.7
Total	38	100.0	39	100.0

Outcome data

Of the 38 women that had saucerization of their VVF, 29 (76.3%) had successful closure of the fistula, while 9 (23.7%) had failed closure. On the other hand, of the 39 women in the dissection group, 36 (92.3%) women had restoration of continence, while only 3 (7.7%) had failed closure, as shown in Table 2. The test of association between surgical technique and outcome of surgery, done using the chi-squared test, was, however, not significant: $\chi^2 = 3.74$, $df = 1$, $p = 0.053$.

Table 2. Outcome of fistula repairs

	Saucerization <i>n</i> (%)	Dissection <i>n</i> (%)
Success	29 (76.3)	36 (92.3)
Failure	9 (23.7)	3 (7.7)
Total	38	39

A review of the 12 failed cases for assessment of residual fistula sizes and the degree of scarring done at 3 months following repair revealed that the residual fistulae were of a larger dimension than the pre-surgery dimension in the saucerization group, unlike in the dissection group, as shown in Table 3. The

mean residual fistula size in the saucerization group was 3.3 (SD 0.8), while for the dissection group, it was 1.7 (SD 0.2).

Table 3. Residual fistulae sizes

	Pre-surgery (cm)	Post-surgery (cm)
Saucerization	3.0	3.5
	3.4	3.8
	3.7	4.1
	4.0	4.5
	2.0	3.0
	2.5	3.1
	3.0	3.3
	0.5	2.0
	1.0	2.5
Dissection	3.0	1.5
	3.5	1.7
	4.0	1.9

Main results

The paired sample *t*-test showed a statistically significant effect from surgery ($t(8) = -4.732$, $p < 0.05$), with an increase in the size of fistulae from pre-saucerization to post-saucerization (mean difference = 0.7444, 95% CI = 0.3816–1.1073). Likewise, in the dissection group, there was a statistically significant effect from surgery ($t(2) = 10.392$, $p < 0.05$), with a decrease in the sizes of fistulae from pre-dissection to post-dissection (mean difference = 1.8000, 95% CI = 1.0548–2.5452). Also, fibrosis (scarring) were found in 7 (77.8%) of the 9 failed cases done by saucerization and in all the 3 (100%) failed cases in the dissection group. The fibrosis was described as moderate to severe.

Discussion

Key results

This study revealed a slightly higher success rate for the dissection method over the saucerization method. The difference, however, was not statistically significant. There was a significant increase in the sizes of residual fistulae for failed cases in the saucerization group, with associated moderate/severe fibrosis.

Interpretation

The WHO proposed a successful closure rate for first repair at 85% in each facility and a continence rate of 90% [17]. Different authors in developing countries have reported a primary fistula closure rate of 61–95% [18]. However, these are largely dissection methods. The closure rate using the dissection method in this study is similar to other studies [17, 18]. A search of published literature on comparison of the saucerization versus dissection technique did not yield any publications. This is the first time this type of study has been carried out to our knowledge. Therefore, it may be reasonable to encourage relatively inexperienced surgeons to use this method (while learning the dissection method) due to the added advantages, which include short operative time, absence of difficult dissection, simplicity and less bleeding [16]. It must be stated, however, that the saucerization method is not suitable for large defects, or when the tissues are not mobile [16]. Prior repair of fistulae, among other factors, have also been shown to be an independent prognostic factor for fistula closure [19]. In spite of the above advantages of the saucerization method, the significant increase in the sizes of residual fistulae for failed cases in the saucerization group, with

the associated moderate/severe fibrosis, are negative prognostic factors for subsequent repair, as supported by other studies [19–21] that showed that both severe vaginal scarring and large fistulae that required extensive dissection to be able to close the defect with the associated postoperative scarring are risk factors for a poor surgical outcome.

Generalizability

The applicability of the findings to the general population is limited due to the small sample size in each group and the need for a similar study in different settings. There is also a need for a more objective method of assessing the degree of fibrosis.

Limitations of the study

The subjective assessment of fibrosis may have caused some imprecision in the assessment of the degree of fibrosis.

Conclusions

The success rate of VVF repair via the saucerization technique is inferior to that of the dissection technique, even though the difference was not statistically significant. Although the saucerization technique is technically easier to perform, the attendant higher failure rate and resultant postoperative increase in size of residual fistulae does not justify its use, especially since the number of failed attempts at repair adversely affect the prognosis.
